Polymorphisms in the Fc Gamma Receptor IIIA and Toll-Like Receptor 9 Are Associated with Protection against Severe Malarial Anemia and Changes in Circulating Gamma Interferon Levels

Department of Biomedical Sciences, School of Public Health and Community Development, Maseno University, Maseno, Kenya; Department of Medical Biochemistry, School of Medicine, Maseno University, Maseno, Kenya; Department of Medical Laboratory Sciences, School of Health Sciences, Masinde Muliro University of Science and Technology, Kakamega, Kenya; Department of Mathematics and Applied Statistics, School of Mathematics and Actuarial Sciences, Maseno University, Maseno, Kenya; and Center for Global Health Research, Kenya Medical Research Institute, Kisumu, Kenya

An understanding of the immunogenetic basis of naturally acquired immunity to Plasmodium falciparum infection would aid in the designing of a rationally based malaria vaccine. Variants within the Fc gamma receptors (FcγRs) mediate immunity through engagement of immunoglobulin G and other immune mediators, such as gamma interferon (IFN-γ), resulting in erythropagocytosis and production of inflammatory cytokines in severe malarial anemia (SMA). The Toll-like receptors (TLRs) trigger transcription of proinflammatory cytokines and induce adaptive immune responses. Therefore, these receptors may condition malaria disease pathogenesis through alteration in adaptive and innate immune responses. To further delineate the impacts of FcγRIIIA and TLR9 in SMA pathogenesis, the associations between FcγRIIIA −176F/V and TLR9 −1237T/C variants, SMA (hemoglobin [Hb] < 6.0 g/dl), and circulating IFN-γ levels were investigated in children (n = 301) from western Kenya with acute malaria. Multivariate logistic regression analysis (controlling for potential confounders) revealed that children with the FcγRIIIA −176V/TLR9 −1237C (VC) variant combination had 64% reduced odds of developing SMA (odds ratio [OR], 0.36; 95% confidence interval [CI], 0.20 to 0.64; P = 0.001), while carriers of the FcγRIIIA −176V/TLR9 −1237T (VT) variant combination were twice as susceptible to SMA (OR, 2.04; 95% CI, 1.19 to 3.50; P = 0.009). Children with SMA had higher circulating IFN-γ levels than non-SMA children (P = 0.008). Hemoglobin levels were negatively correlated with IFN-γ levels (r = −0.207, P = 0.022). Consistently, the FcγRIIIA −176V/TLR9 −1237T (VT) carriers had higher levels of circulating IFN-γ (P = 0.011) relative to noncarriers, supporting the observation that higher IFN-γ levels are associated with SMA. These results demonstrate that FcγRIIIA −176F/V and TLR9 −1237T/C variants condition susceptibility to SMA and functional changes in circulating IFN-γ levels.

Plasmodium falciparum malaria is a complex clinical syndrome comprising a milieu of life-threatening conditions, including severe malarial anemia (SMA), cerebral malaria (CM), metabolic acidosis, high-density parasitemia (≥10,000 parasites/μl), respiratory distress, hypoglycemia, and other less frequent complications, such as hypotension (32). Globally, falciparum malaria accounts for the greatest degree of malaria-related morbidity and mortality (63). The majority of this morbidity and mortality occurs in immune-naïve African children under 5 years of age (11). In western Kenya, SMA (hemoglobin [Hb] < 6.0 g/dl) with any density of parasitemia is the most common clinical manifestation of severe falciparum malaria in pediatric populations resident in regions of transmission holoendemicity (9, 43).

Changes in the human genome have been influenced by pressure due to malaria endemicity—for example, the observed increase in the sickle cell allele (HbAS) in malaria-exposed populations despite its fatal consequences (58). Even though not completely understood, the pathologic mechanisms that underlie SMA may include lysis of infected and uninfected erythrocytes (20, 51), erythrocyte sequestration in the spleen (12, 21), and imbalanced cytokine production in bone marrow suppression (26) and, consequently, dyserythropoiesis (1, 49).

Fc gamma receptors (FcγRs) are a heterogeneous group of hemato poetic cell surface glycoproteins that facilitate the efficiency of antibody-antigen interactions with effector cells of the immune system (17, 27, 52). FcγR genes are mapped to chromosome 1q on 1q21–q23 (17, 27, 52). These receptors regulate a variety of humoral and cellular immune responses, including phagocytosis, degranulation, antibody-dependent cellular cytotoxicity (ADCC), regulation of cytokine expression, activation of B cells, and clearance of immune complexes (23). The FcγR family consists of FcγRI, FcγRII, and FcγRIII (61).

The FcγRs have functional allelic polymorphisms that influence their effector capabilities (61). FcγRIIIA is expressed predominantly on macrophages, monocytes, natural killer (NK) cells, and γ/δ T cells where they function as phagocytic and cytotoxic triggers to antigens (15). It has two codominantly expressed alleles, the −176V and −176F alleles, which differ in the amino acid at position −176 in the extracellular domain (valine or phenylalanine, respectively). The existence of dimorphism in the amino acid position −176 (F/V) of FcγRIIIA has been shown to...
influence the binding of IgG subtypes, with the $-176V$ variant displaying a higher binding affinity for IgG1 and IgG3 compared to the $-176F$ variant (29). In *P. falciparum* infections, IgG1 and IgG3 antibodies have been shown to be associated with low parasitemia and low risk of malaria infection (6). Despite these investigations, the functional role of FcγR variants in regulation of IFN-γ during malaria pathogenesis remains elusive.

Toll-like receptors (TLRs) are type 1 transmembrane proteins that are differentially expressed among immune cells (4, 28). TLRs recognize and bind to conserved pathogen-associated molecular patterns (PAMPs), triggering activation of signal transduction pathways that induce cytokine production (5). TLR9 occupies 5 kb on chromosome 3p21.3 and consists of two exons and contains 1,028 amino acids (22). The PAMPs for TLR9 are hemozoin and unmethylated CpG-DNA (8, 50). Hemozoin, a heme metabolite secreted during malaria infection, activates the innate immune system via a TLR9-mediated MyD88-dependent pathway, resulting in signals that upregulate tumor necrosis factor alpha (TNF-α), interleukin 12p40 (IL-12p40), monocYTE chemoattractant protein 1 (MCP-1), and IL-6 production by dendritic cells (16). Hemozoin is also a carrier that facilitates entry of plasmoidal unmethylated CpG-DNA into the host cell, where the latter can bind to and stimulate TLR9 (48).

Several single-nucleotide polymorphisms (SNPs) that alter susceptibility to infectious and inflammatory diseases have been identified in TLRs. For instance, a study carried out in Ugandan children (aged 3 to 12 years) showed that carriers of a C allele at TLR9 $-1237CC$ or the G allele at TLR9 1174GG were associated with an increased risk of cerebral malaria (CM) since these alleles enhanced production of gamma interferon (IFN-γ) following severe *P. falciparum* infection (53). Studies of pregnant Ghanaian women with *P. falciparum* infection showed that variations in TLR9 $-1486CC$ increased the risk of maternal malaria (35). Other studies investigating the development of premalignant gastric changes induced by *Helicobacter pylori* have identified TLR9 ($-1237T/C$) polymorphism as a risk factor (37). Taken together, these studies demonstrate that TLRs have the capacity to mount acute inflammatory responses against invading pathogens through induction of inflammation.

IFN-γ is a multifunctional cytokine produced by T lymphocytes, B cells, and natural killer cells (NKs). It plays an important role in inflammatory responses and is often associated with the development of overt Th1-like cell-mediated immune responses (25) and hence forms an important part of the immune system. Previous studies with animal models indicated that early production of IFN-γ is necessary for resolution of parasitemia and stimulation of phagocytic cells, leading to clearance of infected erythrocytes (54). Moreover, elevated levels of IFN-γ in the acute phase of uncomplicated *P. falciparum* malaria has been shown to limit progression to clinical malaria (59). Studies in Thai adults demonstrated significantly higher IFN-γ levels in uncomplicated malaria than in individuals presenting with complicated malaria (56). In addition, a previous longitudinal study with a pediatric population in western Kenya demonstrated that high levels of circulating IFN-γ were associated with enhanced SMA severity in a pediatric population (46). Furthermore, studies with animal models have shown that long-term immunity to malaria infection may be affected by an IFN-γ-mediated depletion of parasite-specific CD4$^+$ T cells during infection (64), further demonstrating the critical role of IFN-γ in malaria pathogenesis.

Although FcγRIIIA $-176F/V$ and TLR9 $-1237T/C$ polymorphisms have been implicated in inflammatory diseases (31, 35, 37), to date, no studies have examined the associations between these variants and malaria disease outcomes, specifically in the pediatric population resident in Siaya District, an area of western Kenya where *P. falciparum* transmission is holoendemic. Since previous genetics-based studies have thoroughly investigated SNPs (41, 47) and haplotypes (40, 46), we investigated the effect of cross-SNP combinations in conditioning SMA. We examined the associations between FcγRIIIA $(-176F/V)$ and TLR9 $(-1237T/C)$ promoter-variant combinations and susceptibility to SMA (Hb $< 6.0$ g/dl) in children (aged 3 to 36 months) residing in this area of western Kenya where *P. falciparum* transmission is holoendemic. In addition, we investigated the functional role of these variants in mediating circulating IFN-γ concentrations in children with malaria. The results presented here show that coinheritance of FcγRIIIA $-176F/V$ and TLR9 $-1237T/C$ is associated with susceptibility to SMA and functional changes in circulating IFN-γ levels.

**MATERIALS AND METHODS**

**Study site.** The study was conducted in Siaya District Hospital, western Kenya, and the surrounding community, a region where *P. falciparum* transmission is holoendemic (43). The region is inhabited by the Luo ethnic tribe (>96%), which is hence a homogenous population for genetic-based studies. The prevalence of *falciparum* malaria is ~83% in children aged <4 years, with severe disease manifesting as SMA and/or high-density parasitemia (HDP) (39, 43).

**Study participants.** Children ($n = 301$) of both sexes were recruited in Siaya District Hospital (SDH) in western Kenya during their initial hospitalization for treatment of malaria using questionnaires and existing medical records. Recruitment followed a two-phase tier of screening and enrollment. The parent or guardian of the child received detailed explanation of the study. The enrollment decision was made after initial HIV-1 screening of the child and obtaining informed consent. Questionnaires and written informed consent were administered in the language of choice (i.e., English, Kiswahili, or Dholuo). The children with acute malaria were stratified into two categories. The group with nonsevere malarial anemia (non-SMA) contained children with a positive smear for asexual *P. falciparum* parasitemia of any density, and an Hb level of ≥6.0 g/dl. The SMA group contained children with a positive smear for asexual *P. falciparum*, parasitemia of any density, and an Hb level of <6.0 g/dl (33). Venous blood samples (<3.0 ml) were collected in EDTA-containing Vacutainer tubes at the time of enrollment, prior to provision of treatment or any supportive care. Blood samples were used for malaria diagnosis, hematological measurements, HIV testing, bacterial culture, and genetic analyses. Children were excluded from the study for any one of the following reasons: CM (rare in this area of holoendemicity); a history of any HIV-1-related symptoms, such as oral thrush; clinical evidence of acute respiratory infection; prior hospitalization; intent to relocate during the study period; and unwillingness of the parent or guardian to enroll the child in the study. Participants were treated according to the Ministry of Health (MOH)—Kenya guidelines, which included the use of oral artemether-lumefantrine (Coartem) for uncomplicated malaria and intravenous quinine (and on rare occasions, blood transfusion) for severe malaria. The study approval was obtained from the Ethics Review Committee of the Kenya Medical Research Institute (KEMRI). Informed written consent was obtained from the parent or legal guardian of all children participating in the study.

**Laboratory procedures.** Hemoglobin levels and complete blood counts were determined using the Beckman Coulter ACT diff2 (Beckman–Counter Corporation, Miami, FL). To determine parasitemia, 10% Giemsastained thick blood smears were prepared and examined under a microscope at high-power magnification. The number of *P. falciparum* parasites per 300 white blood cells (WBC) was determined, and parasitemia (number of parasites per microliter) was estimated using the total.

a Data are shown as the median (with interquartile range [IQR] in parentheses) unless otherwise noted. Children with parasitemia (n = 301) were stratified according to a modified definition of SMA based on age- and geographically matched Hb concentrations (i.e., Hb, <6.0 g/dl with any density of parasitemia) (33) into non-SMA (n = 163) and SMA (n = 138). HDP, high-density parasitemia.

b Statistical significance determined by χ2 analysis.
c Statistical significance determined by the Mann-Whitney U test.

WBC count. In order to delineate severe anemia caused by malaria versus other anemia-promoting conditions, HIV-1, bacteremia, sickle-cell trait (HbAS) status, and glucose-6-phosphate dehydrogenase (G6PD) deficiency were determined. Pre- and posttest HIV counseling was provided for all participants. HIV-1 exposure and infection were determined serologically (i.e., with Unigold and Determine) and through HIV-1 proviral DNA PCR testing, respectively, according to previously published methods (45). Bacteremia was determined using the Wampole Isostat Pediatric System (Whitney U test was used for comparisons of demographic and clinical characteristics and circulating IFN-γ levels between the clinical groups (Table 2). The distributions of gender, parasitemia (parasites/μl), proportions of subjects with high-density parasitemia (HDP), and axillary temperature (°C) were not significantly different between the groups (P = 0.668, P = 0.508, P = 0.456, and P = 0.109, respectively) (Table 1). Children presenting at the hospital with SMA were younger than those with non-SMA (P = 0.010). With reference to previous grouping, the Hb (g/dl) concentration and erythrocyte counts (1012/liter) were lower in the SMA group (P < 0.001) for the two clinical parameters (Table 1).

**RESULTS**

Clinical, demographic, and laboratory characteristics of the study participants. A cross-sectional analysis in children (n = 301, aged 3 to 36 months) presenting with acute *P. falciparum* malaria (any density of parasitemia) was performed. Clinical stratification of the study groups was done based on a previous age- and geographically defined reference population from western Kenya (33), i.e., nonsevere malaria (non-SMA) (Hb ≥ 6.0 g/dl; n = 163) and severe malaria anemia (SMA) (Hb < 6.0 g/dl; n = 138). The distribution of gender, parasitemia (parasites/μl), proportions of subjects with high-density parasitemia (HDP) (≥10,000 parasites/μl), and axillary temperature (°C) were not significantly different between the groups (P = 0.668, P = 0.508, P = 0.456, and P = 0.109, respectively) (Table 1). Children presenting at the hospital with SMA were younger than those with non-SMA (P = 0.010). With reference to previous grouping, the Hb (g/dl) concentration and erythrocyte counts (1012/liter) were lower in the SMA group (P < 0.001) for the two clinical parameters (Table 1).

**Distribution of FcγRIIIA (−176F/V) and TLR9 (−1237T/C) genotypes and alleles in the clinical groups.** To investigate the role played by the polymorphic variation in the FcγRIIIA (−176F/V) and TLR9 (−1237T/C) promoters in conditioning susceptibility to SMA, their allelic distributions were compared between the clinical groups (Table 2). The distributions of FcγRIIIA −176F/V genotypes in the overall population were 54.5% FF, 36.5% FV, and 9.0% VV, with overall allele frequencies of 0.72 for F and 0.28 for V. However, the overall allele frequency for FcγRIIIA −176F/V did not deviate from the Hardy-Weinberg equilibrium (HWE) (χ2 = 1.83, P = 0.180). The prevalences of FcγRIIIA −176F/V genotypes in non-SMA were 52.2% FF, 36.8% FV, and 11.0% VV with allele frequencies of 0.71 for F and 0.29 for V, while the genotypic distributions of FcγRIIIA −176F/V in the SMA group were 57.3% FF, 36.2% FV, and 6.5% VV, with allele frequencies of 0.75 for F and 0.25 for V. The allele combinations, and SMA were determined by multivariate logistic regression, controlling for the confounding effects of age, gender, HIV-1 status (including HIV-1-exposed and definitively HIV-1− results), glucose-6-phosphate dehydrogenase (G6PD) deficiency, sickle cell trait (HbAS), and bacteremia. The correlation between IFN-γ concentrations and Hb levels in parasiticemic children was determined by Spearman’s correlation coefficient. Statistical significance was set at P ≤ 0.05.

b Data are presented as n (%) children. Children with parasitemia were categorized on the basis of the presence or absence of severe malarial anemia (SMA) (defined as Hb < 6.0 g/dl with any density of parasitemia) (33).

c Statistical significance determined by χ2 analysis.
significantly deviate from HWE. The distribution of the TLR9 \((-1237T/C)\) genotype in the overall study population was 40.9% TT, 49.8% TC, and 9.3% CC (Table 2), with overall allele frequencies of 0.70 for T and 0.30 for C. There was no significant departure from the HWE in the overall study population (\(\chi^2 = 5.00, P = 0.040\)). The genotypic distributions in the non-SMA group were 36.8% TT, 54.4% TC, and 9.8% CC (Table 2), with allele frequencies of 0.63 for T and 0.36 for C. The allele frequency in the non-SMA group demonstrated a significant departure from the HWE (\(\chi^2 = 4.00, P = 0.040\)).

Additional \(\chi^2\) analysis showed that the distributions of the individual Fc\(\gamma\)RIIA \(-176F/V\) and TLR9 \((-1237T/C)\) genotypes were comparable between the SMA and non-SMA groups (\(P = 0.356\) and \(P = 0.297\), respectively).

**Influence of polymorphic variability in Fc\(\gamma\)RIIA \(-176F/V\) and TLR9 \((-1237T/C)\) on SMA.** The association between individual genotypes of Fc\(\gamma\)RIIA \(-176F/V\) and TLR9 \((-1237T/C)\) and susceptibility to SMA was determined using multivariate logistic regression analyses while controlling for the confounding effects of age, gender, HIV-1 infection, sickle cell trait (Hb\(\alpha\)S), bacteriaemia, and G6PD deficiency (3, 45, 62). No significant associations were observed between the variations at individual loci of Fc\(\gamma\)RIIA \((-176F/V)\) and TLR9 \((-1237T/C)\) and susceptibility to SMA (Table 3).

**Distribution of Fc\(\gamma\)RIIA \(-176F/V\) and TLR9 \((-1237T/C)\) SNP combinations in the clinical groups.** As shown in Table 4, cross-gene SNP combination for the receptor polymorphisms yielded the following overall prevalences in the non-SMA and SMA groups (33): Fc\(\gamma\)RIIA \(-176F/TLR9 = 1237T (FT), 80.1% (241/301); Fc\(\gamma\)RIIA \(-176V/TLR9 = 1237C (VT), 26.6% (80/301); and Fc\(\gamma\)RIIA \(-176V/TLR9 = 1237C (VC), 24.0% (74/301). Additional comparison showed a higher proportion of carriers of the \(-176V/-1237T (VT)\) SNP combination in the SMA group (33.3%) compared to the non-SMA group (20.9%; \(P = 0.015\)). Consistent with this observation, the VT carriers presented with significantly lower Hb levels (median, 5.70 g/dl; interquartile range [IQR], 3) relative to the non-VT carriers' median (6.70 g/dl; IQR, 3) (\(P = 0.001\)). In agreement with this finding, carriers of this SNP combination also had significantly higher Hb levels (median, 6.70 g/dl; IQR, 3) compared to the noncarriers (median, 5.60 g/dl; IQR, 3) (\(P = 0.002\)). Further analysis revealed comparable proportions and Hb levels for the \(-176F/-1237T (P = 0.887)\) and \(-176F/-1237C (P = 0.588)\) and \(-176F/-1237C (P = 0.490)\).

a Children with acute malaria (n = 301) were stratified according to the modified definition of severe malarial anemia (SMA) based on age- and geographically matched Hb concentration (i.e., Hb < 6.0g/dl with any density of parasitemia) (33). Odds ratios (OR) and 95% confidence intervals (CI) were determined using multivariate logistic regression analysis. Controls were non-SMA (n = 70). The boxes represent the interquartile range; the lines through the boxes are the medians, while the whiskers show the 10th and 90th percentiles. Shaded boxes show children with SMA, while open boxes are non-SMA children. Non-SMA children had significantly lower circulating IFN-γ levels relative to SMA children (P = 0.008, Mann-Whitney U test).

Association between circulating IFN-γ and FcγRIIIA −176F/V and TLR9 −1237T/C promoter polymorphisms. To determine whether these genotypes were associated with functional changes in concentrations of IFN-γ levels, plasma levels of IFN-γ were compared across the genotypic groups. As presented in Fig. 2A and B, there were no significant differences in the concentrations of plasma IFN-γ across genotypes for both FcγRIIIA (−176F/V; FF, 77; FV, 53; and VV, 9) (P = 0.480) and TLR9 (−1237T/C; TT, 65; TC, 65; and CC, 9) (P = 0.559). The distributions of IFN-γ in the FcγRIIIA −176F/V genotype were as follows: FF, median, 19.6, and IQR, 30.6; FV, median, 15.9, and IQR, 28.1; and VV, median, 19.6, and IQR, 27.3. The distributions of IFN-γ in the TLR9 (−1237T/C) genotype were as follows: TT, median, 16.2, and IQR, 34.6; TC, median, 19.6, and IQR, 33.6; and CC, median, 14.0, and IQR, 27.5.

Functional associations between FcγRIIIA −176F/V and TLR9 −1237T/C SNP combinations and circulating IFN-γ levels. To determine whether coinheritance of these receptor polymorphisms was associated with changes in IFN-γ levels, circulating
malaria (6, 57). We are currently exploring this model to test whether carriage of this variant is associated with higher IgG binding in children naturally exposed to P. falciparum malaria in a region of holoendemicity in western Kenya, in which the primary clinical outcome of severe malaria is SMA.

There is accumulating evidence on the potential role of TLR9 polymorphisms in clinical malaria (13, 30, 65). Consistent with our study, two separate studies, carried out in Brazil and Iran, have recently revealed no impact of individual TLR9 (−1237T/C) promoter polymorphism on susceptibility to mild malaria in their respective populations (30, 65). Moreover, the TLR9 (−1237TT) genotype has only been associated with low parasitemia but not increased susceptibility to clinical malaria in Ghanaian children aged 3 to 11 years (40). Investigations with Gambian and Malawian children less than 5 years old characterized by mixed clinical phenotypes (cerebral and/or severe malaria anemia) did not show any association between the TLR9 (−1237T/C) polymorphisms and severe malaria (13). However, a study of Ugandan children (aged 4 to 12 years) showed that the TLR9 (−1237CC) genotype was associated with elevated levels of plasma IFN-γ and enhanced cerebral malaria (53), emphasizing the fact that these variants may individually be associated with CM rather than SMA. Moreover, other studies have revealed that individuals infected by malaria have upregulated TLR9 and elevated IFN-γ and that mice with TLR9 gene knockout produce low IFN-γ levels in response to Plasmodium chabaudi AS (24). The discrepancies observed between our study and others may in part be explained by the difference in clinical phenotypes since in our study population, the main clinical manifestation is SMA in pediatric populations, while the earlier studies focused on heterogeneous populations in which the most severe clinical manifestation was CM. In addition, pathways of TLR9 signaling involve polymorphisms in the downstream molecules (for instance, NF-κB and MyD88) that were not investigated in the present study. Furthermore, due to the high prevalence of malaria in our population and the fact that TLRs only act in recognition and induction of the immune response, we assume that polymorphisms in the TLRs are not the primary determinants of clinical malaria. We are currently investigating additional genes that may significantly alter TLR pathways and alter malaria disease susceptibility.

Since susceptibility to infectious disease occurs through multifactorial, complex, and even contradictory selective pressures (7), our laboratory constructed cross-SNP combinations between FcγRIIA (−176F/V) and TLR9 (−1237T/C) in an attempt to determine whether coinheritance of these receptor-SNP combinations could influence susceptibility to SMA. Based on results from this study, carriage of the −176V/−1237C (VC) SNP combination was associated with reduced susceptibility to the development of SMA relative to noncarriers. Consistent with this observation, carriers of VC had concomitantly higher levels of circulating IFN-γ (46). Since FcγRIIA is mainly expressed on the macrophages and monocytes, they play a primary role in phagocytosis of unparasitized erythrocytes and induction of proinflammatory cytokines, which play a role in SMA pathogenesis (10). On macrophages, FcγRIIA is also involved in the clearance of immune complex (15). Consistent with a previous study with Thai adults (41), the individual FcγRIIA −176F/V polymorphism failed to show any association with SMA. However, it is important to note that this polymorphism influences preferential binding of IgG in which FcγRIIA (−176V/V) has higher binding affinity to IgG1 and IgG3, which are associated with low parasitemia and low risk of

**FIG 3** Association between circulating IFN-γ levels and FcγRIIA −176F/V and TLR9 (−1237T/C) SNP combinations. Data are represented in box plots for FcγRIIA −176F and TLR9 −1237T (FT, 121), FcγRIIA −176V and TLR9 −1237C (VC, 106), and FcγRIIA −176V and TLR9 −1237T (VT, 104), and FcγRIIA −176V and TLR9 −1237C (VT, 106). The boxes represent interquartile ranges; the lines through the boxes are the medians, while the whiskers show the 10th and the 90th percentiles. Pairwise comparisons in those with and without the combination were done using the Mann-Whitney U test. Shaded boxes show children with the indicated SNP combination, while open boxes show those without the combination. Carriage of FcγRIIA−176V/TLR9−1237T (VT) SNP combination was associated with significantly higher levels of circulating IFN-γ relative to that in noncarriers (P = 0.011).
lating IFN-γ levels are associated with SMA in this population. As such, any gene combination that may be associated with higher circulating IFN-γ levels may promote SMA. It would be plausible to explore how different cytokine milieu in relation to IFN-γ levels and IgG production promote the development of SMA over time in this pediatric population resident in western Kenya. This approach will address the inherent limitation in examining cytokine production at a single time point (time of admission) and in circulation rather than in the local microenvironments, which in essence complicates the clear understanding of the exact role of immune mediators such as IFN-γ in SMA (34). This study underscores the importance of the use of cross-SNP combinations in genetic association studies of infectious diseases such as malaria because it reveals associations that are not identifiable with just single gene polymorphisms since such disease outcome(s) are dictated by genes functioning in concert (2).

It is worth noting that substitution of a T for a C in TLR9 − 1237 in the SNP combination (VC versus VT) significantly determined whether individuals were increasingly susceptible or had reduced risk to SMA in children who presented with acute malaria. Activation of gene transcription depends upon the binding of regulatory and transcription factors to specific recognition sequences in the promoter. As such, variation in the TLR9 − 1237T/C promoter sequences likely alters specific transcription factor recognition sites and consequently affects transcriptional activation of IFN-γ and production of other effectors during acute disease. For example, the presence of a T at the TLR9 − 1237 locus (VT in the SNP combination) may favor enhanced binding of transcriptional factors (or cause disruption of repressor binding sites) that lead to higher IFN-γ production, whereas, the presence of the C in the promoter (VC in the SNP combination) may create sites for enhanced binding of repressors that favor reduced IFN-γ production. Although the impact of the surface receptor-SNP combinations examined here on promoter binding elements is largely unknown, our laboratory is currently investigating the mechanism(s) by which these cross-SNP combinations may alter IFN-γ production.

Despite continued investigations, the exact role of IFN-γ in the pathogenesis of SMA continues to be baffling. For example, high early IFN-γ production has been shown to confer protection against symptomatic malaria episodes in children aged 5 to 14 years from a region of malaria endemicity of Papua New Guinea (19). An additional study in an area of holoendemic perennial *falciparum* malaria transmission in southern Ghana reported that malaria-specific production of IFN-γ was associated with reduced clinical malaria and fever (18). Collectively, these studies implicate increased IFN-γ production in clinical malaria. However, certain studies have reported an association between higher levels of IFN-γ and severe malaria. For instance, a study in Uganda reported a positive association between increased IFN-γ levels and CM (53). Furthermore, a previous report on a population of children resident in western Kenya demonstrated that IFN-γ was a positive predictor of SMA (42). The results presented in the present study versus those from the previous study (42) likely differ due to differences in the stratification of the cohort groups. In the present study, we stratified our study population into the SMA group (Hb < 6.0 g/dl with any density of parasitemia) and non-SMA groups (Hb ≥ 6.0 g/dl with any density of parasitemia), whereas the previous study (42) further stratified the overall non-SMA group (Hb > 6.0 g/dl with any density of parasitemia) into uncomplicated malaria (UM) (Hb levels of >11.0 g/dl; n = 31) and non-SMA (Hb levels of 6.0 to 10.9 g/dl; n = 37) for the least-angle regression (LAR) analyses. In addition, potential underlying genetic variations that may potentially contribute to differences in functional changes (e.g., IFN-γ) during disease in the population were never controlled for as a variable in the LAR analyses. In the present study, we demonstrate that children with SMA had significantly higher IFN-γ concentrations, a finding consistent with a previous study of the same population (46). Even though not explicitly explored, the pathogenic mechanisms of elevated IFN-γ in SMA may in part be a consequence of overstimulation of monocytes by IFN-γ to secrete TNF-α (44). This stimulation would lead to the formation of toxic oxides and free radicals, such as reactive oxygen species (H₂O₂ and inducible nitric oxide synthase [iNOS]), by liver cells against intrahepatic parasites and erythrocytic-stage parasites (38, 55, 60), as well as enhanced phagocytic activities of monocytes/macrophages against parasitized and non-parasitized erythrocytes (36). Moreover, overproduction of IFN-γ also promotes enhanced malarial anemia pathogenesis through bone marrow suppression, dyserythropoiesis, and erythropagocytosis (14). However, for enhanced immunity to be accomplished, milieu of balance of both proinflammatory and anti-inflammatory cytokines are involved (18) and should be considered in future study designs.

In summary, our results demonstrate that SMA in this pediatric population is conditioned by functional variations in FcyRIIIA (−176F/V) and TLR9 (−1237T/C) promoter polymorphisms. To exhaustively describe the impacts of surface receptors in development of naturally acquired immunity against malaria, further longitudinal studies aimed at examination of an all-inclusive panel of receptor polymorphisms that influence innate immune response and disease outcome are required as this may provide an immunogenetic basis for the development of vaccines that modulate receptor functions.

**ACKNOWLEDGMENTS**

We are grateful to the Siaya District Hospital for clinical support. We are indebted to the parents/guardians of the study participants and children who took part in the study. This work was published with the approval of the Director, KEMRI.

This work was supported financially by grants from the National Institutes of Health (7R01-TW008306-05).
